## INTRODUCTION

Introduction

### ***1.1 Background***

#### **1.1.1 Social Spaces**

According to Lam [31], mobile robots should obey certain rules while navigating in human environments. These rules include: not colliding anybody, not entering the personal space of a human unless the task is to approach the human and waiting if robot unwillingly enters the personal space of a human. Humans are already good at obeying such social conventions. Therefore most works on robot navigation in human environments is linked to human-human spatial interactions. One of the first studies in such interactions is conducted by Hall [18]. This study presents the proxemics theory, which categorizes the distance between people in four classes. These distances, named intimate, personal, social and public, provide spatial limits to different types of interactions. Kendon [22]’s F-formation is based upon observations that people often group themselves in a spatial formation, e.g. in clusters, lines and circles. Some works adopted Hall distances and Kendon’s formations for human-robot interaction. Huttenrauch [20] found that personal distance between a robot and a person varied in the range of 0.45 to 1.2 meters and but claimed that works of Hall and Kendon should be adapted to suit the dynamics of HRI. Avrunin [3] aims to learn acceptable distances from human-human experiments in an approaching scenario.

## CHAPTER II

### MAP ANNOTATION

#### Map Annotation

In mobile robotics, the standard practice for mapping and localization is described as follows: When the robot is first taken to a new environment, it has to map the environment. There has been extensive research on Simultaneous Mapping and Localization (SLAM) literature. The usual output is a binary 2D grid map where 1s represents an obstacle and 0s represent free space. Once the map is created, the robot can localize itself in the map while in operation. Every time the robot is restarted, it has to start with an initial estimation of its location. Although there are global localization methods developed in the community, the usual practice is that the robotics expert manually provides an approximate initial location of the robot, then the localization method corrects the localization estimation as the robot moves in the environment.

## CHAPTER III

### NAVIGATION AMONG PEOPLE

Autonomous navigation is one of the most fundamental tasks for a mobile robot. For a mobile robot with adequate actuation and sensing, collision-free navigation is considered a solved problem. There are many algorithms that achieve point-to-point autonomous navigation thanks to the advances in the motion planning community. Many of these algorithms are optimized to find the least-cost path, or the shortest path. However, when there are humans in the environment, such algorithms suddenly become inefficient or insufficient. For example, while it is acceptable for a robot to get inches close to a wall, doing so to a human is socially unacceptable and potentially dangerous. Similarly, sudden appearance of a robot can surprise or shock humans. There are many other social scenarios where the shortest path may not be optimal.

In addition to sub-optimality, these approaches may be incomplete in the sense that they can not find a solution even though there is a feasible one. This is because shortest-path navigation algorithms treat every object in the environment as an obstacle. This assumption does not hold when intelligent agents are present in the environment. Therefore navigation should differentiate humans and obstacles for more intelligent robot behavior.

Another aspect to spatial interaction between humans and robots is the dynamics of the robot motion. For example, people may feel uncomfortable and unsafe when they are in close proximity to high-speed agents or objects. Therefore, for a robot in a human environment, while it may be acceptable to speed up in dedicated regions, its speed should be limited in places where there is a significant possibility of encountering a human.

In this Chapter, we first provide a background and present the most common approach in contemporary autonomous navigation methods in Section 3.1. Second, we provide relevant works on navigation among people in Section 3.2. Third, in Section 3.3, we present how the goal points for navigation are determined. We then present our people-aware navigation method in Section 3.4. Lastly, we touch to the subject of introducing speed limits for all robots in a human environment in Section 3.5.

### ***3.1 State-of-the-Art Approach in Autonomous Navigation***

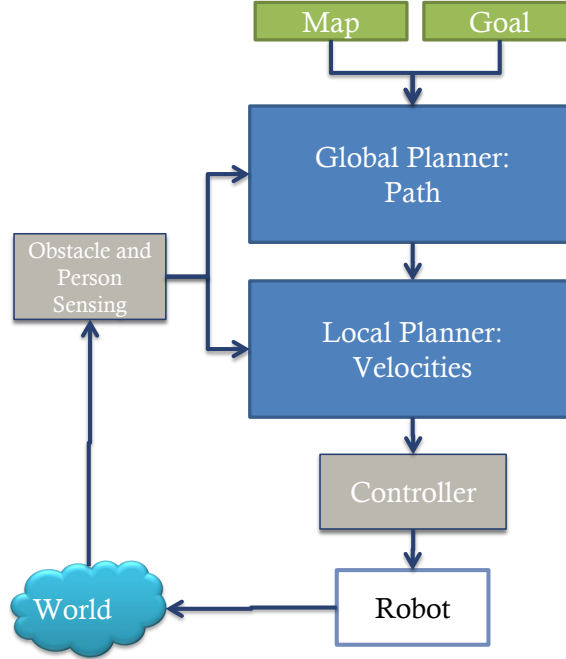

There are two prerequisites that enables autonomous navigation:

1. The map of the environment, usually in the form of a discrete grid, that represents static objects in the environment
2. A way to localize the robot in the map using sensory information as it moves in the environment

Robot navigation involves finding a collision-free path from a start pose  $(x_0, y_0, \theta_0)$  to a goal pose  $(x_g, y_g, \theta_g)$ . In real-time operation,  $(x_0, y_0, \theta_0)$  is the robot's current pose as the robot tries to reach to the goal pose from where it currently is.  $\theta_g$  is optional as the goal of the robot could be to reach the goal position regardless of its orientation. The goal position is provided from an external process, and we will touch upon how the goal positions are calculated in Section 3.3.

A common approach to path planning is to divide the path planning into two parts: *global* and *local*. Global planning aims to find a path from the start position to the goal position. The global path is a set of consecutive positions that connect the start to goal position. A global path is usually found with a search algorithm executed on a graph of points. The search heuristics is dependent on specific global planners, and in most cases collision-free shorter paths are favored. The local planner is responsible

**Figure 1:** Caption

to execute the global path by calculating a trajectory and sending velocity commands to motor controllers. As the robot acts in the environment, its sensors sense the new state of the robot and people, and the new iteration begins. This cycle is shown in Figure 1.

A popular method to implement the global and local planners is by using a *costmap*. A *costmap* not only has the same representation as the map, however collision-free positions can have non-zero costs. A lower cost cell is more favored to be in to a higher cost cell. After the calculation of all cells, the least-cost path is found that connects the start position to the goal position.

Note that this approach assumes the robot is able to execute any path provided to it. Holonomic robots can move in any direction, however non-holonomic robots has limitations in their movements. For example, two wheel robots can not move sideways. Two common approaches to solve this problem are: to implement trajectory planners that can handle imperfect control or to embed the robot's dynamics into sampling for global and local planning.

## **3.2 *Related Work***

In this section, we review the literature on robot navigation in human environments including socially acceptable navigation, learning behaviors from humans and cooperative navigation.

### **3.2.1 Socially Acceptable Path Planning**

Socially acceptable robot navigation is considered in different applications such as free navigation [54], approaching people [48] and evacuating buildings [41]. Some works used the personal space concept in cost-based general path planners [54, 25]. Sisbot [54] models the social spaces as a ellipse-shaped Gaussian, and takes into account the safety, preferences and vision fields of humans for a robot that navigates from a location to another. Kirby [25] presents a path planner that takes into account social conventions such as tending to one side of the hallways. A potential field based trajectory planner for dynamic human environments is presented by Svenstrup [57]. Rios-Martinez [45] presents a RRT-based planner that considers not just safety but also the disturbance of humans. In simulation, if interaction within a group of people is detected, the robot can either not disturb the interaction or join the group. This approach is implemented on a wheelchair robot [62]. Althaus [1] presents a robot that can join a group of people and adjust to the formation reactively. The scenario where a robot encounters a human in a hallway is studied by Pacchierotti [42]. Parameters such as the distance between the human and the robot when the robot begins to deviate from its path and lateral distance that robot should be placed when it is passing the human are found from experiments. Recent work by Lu [34] showed that using gaze cues and social navigation makes robot-human hallway passing more efficient.

### 3.2.2 Learning Navigation from Human Behavior

Behaving human-like in robot navigation is usually favored in the literature [47]. One way to simulate human navigation behavior is to use social cost maps that capture social conventions [49, 35]. Contrary to the imitation approach, [7] tries to avoid predicted paths, with the goal to minimize the risk of interference. Kuderer [30] presents a tele-operated robot that computes the policy of a desired interactive navigation by learning from observations of pedestrians. Pellegrini [43] trains a dynamic social behavior, that account for social interactions, using pedestrian data.

### 3.2.3 Human Cooperation in Robot Navigation

Robots can exploit human cooperation in certain scenarios. In populated environments, one way to move with the crowd is to follow individuals that move towards the robot’s goal [56, 39].

Some of the recent works in the literature claim that the robot motions should be predictable so the human observers can judge the motive and future behavior of the robot. Observational study in [33] claims that three features can increase the predictability of robot navigation: straight lines, stereotypical motions and usage of additional gestures. In a user study conducted by Gockley [17], humans observers watched two ways of person following. People found direction-following more natural than exact path following. Kruse [28] observes that when paths of two humans are crossed at a right angle, they adapt their velocity rather than the path. This behavior is implemented on a robot, resulting in more predictable motions.

Trautman [59] introduces the ‘freezing problem’, where traditional path planners fail to produce a feasible solution in crowded human environments. Muller [39] briefly mentions a ‘shooing away’ behavior, where the robot accelerates towards a human, hoping that he/she will get out of the way. Kruse [29] introduces an optimistic planner, which assumes that people will cooperate with robot movements. Their

approach relies on assigning a non-infinite cost if a robot enters to a human's personal space, however the plan fails if humans doesn't move as expected because of the lack a local planner.

### ***3.3 Goal Points for Navigation***

As presented in Section TODO, our interactive system allows a user to annotate planar landmarks and tabletop objects.

People Aware Navigation

### ***3.5 Speed Limits for Safe Navigation***

Speed Maps for Safer Navigation

## CHAPTER IV

### MULTIMODAL PERSON DETECTION AND TRACKING

The ability to robustly track a person is an important prerequisite for human-robot interaction. To realize any task that involves humans, the challenge is the detection and tracking of humans in the vicinity of the robot considering the robot’s movements, sensing capabilities and occlusions. The scope of how much information is needed from the human perception module depends on the objective of the application. First, the robot should determine if there are people nearby. If the robot senses people around, the robot should find out *where* they are. Representing people as points (x,y) in maps is common practice for navigation planning. If the task requires the robot to face a person, then the orientation  $\theta$  needs be detected. The robot further can determine *who* the detected person is. Identification of humans is necessary for enabling non-generic service. Finally, the robot should interpret *what* the person is doing by analyzing the motion features and through gesture analysis. Tracking body parts of humans over time give significant information about human activity.

We focus on tracking people who are either walking or standing, as these are the two most common human poses around a mobile robot. Many full-body or body part detectors have been developed in the literature, reviewed in Section 4.1. Full-body detectors are not suitable for mobile robot navigation applications because of their inability of capturing the entire body with on-board sensors when people are close to the robot. We aim to robustly track a person 360° around the robot. However, most sensors have a limited field of view and using only a single detector can lead to a system with a single point of failure. Therefore, we think a multimodal detection system is better suited for on-board people tracking for our use cases.

Laser scanners are the natural sensor of choice as state-of-the-art mobile robots are already equipped with an ankle-height laser scanner that is mainly used for navigation. The laser scanners we used on our robot are Hokuyo UTM 30-LX, which has  $270^\circ$  Field of View (FOV),  $0.25^\circ$  angular resolution,  $40Hz$  refresh rate and  $30m$  maximum range. We are only interested in detections in close range (less than  $5m$ ). In that range interval, and the accuracy of each laser reading is  $\pm 3cm$ , which is sufficient for our use cases. The relatively higher accuracy and resolution are the two advantages of laser scanners over cameras and RGB-D cameras. Cameras, on the other hand, have the advantage of providing richer information, which can be used to extract body parts. We use a combination of detectors using either a laser scanner and RGB-D camera for robustness and better coverage, described in Section 4.2. Representing people as a points in the map is sufficient for mobile robot navigation and each detector produces a point as a person hypothesis. We use a real-time probabilistic tracking framework that relies on the fusion of the multiple person detections, described in Section 4.3. For certain applications, identifying specific users allows the robot to go beyond generic capabilities. We present our face recognition method in Section 4.4.

## 4.1 *Related Work*

Person detection was first addressed by the computer vision community as an object detection problem. Early research on person detection using vision is surveyed by Moeslund [37]. Face detection is a common method for detecting people, with the work of Viola and Jones [63] being the most popular one. See Zhang [66] for a survey on contemporary approaches on vision based face detection. Another popular topic has been pedestrian detection in crowded scenes Leibe [32] and Tuzel [61].

In 2000's, laser scanners became the de-facto sensor for localization and mapping. Laser scanners are usually placed slightly above floor for obstacle avoidance, therefore leg detection is common practice. Early works by Montemerlo [38] and Schulz [50]

focused on tracking multiple legs using particle filters. Legs are typically distinguished in laser scans using geometric features such as arcs [64] and boosting can be used to train a classifier on a multitude of features [2]. Topp [58] demonstrates that leg tracking in cluttered environments is prone to false positives. For more robust tracking, some efforts fused information from multiple lasers such as Carballo’s work [10], which uses a second laser scanner at torso level. Glas [16] uses a network of laser sensors at torso height in hall-type environments to track the position and body orientation of multiple people. Several works used different modalities of sensors to further improve the robustness. Kleinhagenbrock [27] and Bellotto [6] combine leg detection and face tracking in a multi-modal tracking framework. Other examples include combining sound localization and vision [8] and combining RFID tracking and vision [15].

Laser-based person methods pertains tracking of humans in 2D, projected to floor plane. Tracking of the body parts has long been a topic of interest in vision [5, 52]. With the recent introduction of 3D sensors such as the Velodyne, Swissranger and Kinect, more robust tracking became possible. Spinello [55] trains geometrical features at different height levels in the 3D point cloud for pedestrian detection. Ganapathi [13] estimates body part locations with a probabilistic model. One of the well-known skeleton tracking algorithms is the Microsoft Kinect SDK by Shotton [51], which trains decision forests using simple depth features in a vast database. This software is not suitable to work on a mobile robot as it is designed to work on a stationary sensor. In the robotics community, there are efforts to develop skeleton trackers that work on mobile robots and in unstructured scenes [9].

Face recognition is a widely used application as surveyed by Phillips [44]. One of the pioneers in face recognition uses a set of patch masks for features that doesn’t necessarily correspond to eyes, ears or noses [60]. [67] combines PCA (Principal

Component Analysis) and LDA (Linear Discriminant Analysis) to improve the generalization capability when only a few samples are available.

There has been some work to identify humans using 3D data, such as the head-to-shoulder signature [26] and body motion characteristics [40]. Biometric person identification techniques, such speaker recognition [24], 3D ear shape [65] and multi-modal cues [14] have potential to be more accurate than face recognition. However, these approaches are better suited to work in controlled environments.

## 4.2 *Person Detection*

In this section, we present our person detectors, namely leg detection (Section 4.2.1) and torso detection (Section 4.2.2). We also use an implementation of an upper body detector by Mitzel [36], which uses a template and the depth information of a RGB-D camera to identify upper bodies (shoulders and head), designed to work for close range human detection using head mounted cameras.

### 4.2.1 Leg Detection

A front-facing laser scanner at ankle height is used for leg detection. The output of a laser scanner at each iteration is an array of range measurements, represented in the polar coordinate system. We first convert the range data to Cartesian coordinate system:

$$x_i = \sum_{\phi=\phi_{start}}^{\phi_{end}} r_i \cos(\phi)$$

$$y_i = \sum_{\phi=\phi_{start}}^{\phi_{end}} r_i \sin(\phi)$$

Then we apply segmentation, Segmentation produces clusters of consecutive scan points, which due to their proximity, have a high likelihood of belonging the same object. Two adjacent distance measurements are considered to be in the same segment if the Euclidean distance between them is below a threshold value. Starting from the

start of the range array, a new segment is started if  $|r_i - r_{i+1}| < d_{cluster}$ . Although some approaches use a variable segmentation threshold that is a function of the range, we use a fixed clustering threshold  $d_{cluster} = 0.1m$ . The segmentation process results in a set of segments  $\mathbf{S}$ . A set of geometric features are extracted from the laser segment.

In a laser scan, legs can appear in different patterns [58]. We look only single leg and person-wide blob patterns as these two cover all the ways legs can be seen in a laser scan. Depending on the application, we accept either only the single leg pattern or both of the patterns (explained in Section ??).

There are a number of geometric features that can be extracted from a laser segment, as delineated by Arras [2]. We use three geometric features that is used to detect a leg: segment width, circularity, and Inscribed Angle Variance (IAV):

1. Segment Width: Measures the Euclidean distance between the first and last point of a segment  $S_i$
2. Segment Circularity: This measure is a simple measure to assess if the segment shape resembles a circle. The circularity criterion we used is the ratio of the perpendicular distance from the middle point to the line segment that connects start and end points, to the segment width. For example, in a perfect half circle in Figure 2, the circularity criterion is  $|\overline{P_0 P_n}|/d_{mid} = 0.5$ . In case of a laser scan, as can be seen in Figure 3, we again consider the ratio of  $d_{mid}$  to segment width. For this calculation we only consider the middle point as it provides a simple heuristic on circularity.
3. Inscribed Angle Variance (IAV): This feature is originally proposed by Xavier [64], in order to detect circles. We adopt IAV in order to detect legs, which are not necessarily circle-shaped, especially for the person-wide blob pattern. As an example, inscribed angles on a circle is shown in Figure 4. As a geometric

**Figure 2:** Circularity criterion in a perfect circle is:  $|P_0P_n|/d_{mid} = 0.5$

**Figure 3:** Circularity criterion in a laser segment is:  $|P_0P_{10}|/d_{mid}$

property of the circle,  $\angle P_0P_1P_4$  and  $\angle P_0P_2P_4$  are equal angles. IAV for a given set of points is the average of all inscribed angles:

$$IAV_S = \sum_{P=P_1}^{P_{n-1}} \angle P_0PP_n$$

For a perfect circle,  $IAV_S = 90^\circ$ . For shapes that are not perfect circles but are similar to circles, IAV feature should be consistent. Laser segments from a leg usually resemble a circle, therefore we use IAV as one of the features for leg detection.

**Figure 4:** Inscribed angles of an arc are shown in the figure. Inscribed Angle Variance (IAV) is calculated by taking the average of all inscribed angles on a laser segment.

In order to be able to use these values, we first found the nominal feature values for an average human leg. We captured the laser scan data while the robot followed a person through an office environment. The following method used for this experiment will be discussed in detail in Section 5.2. For the training set, two people's legs were recorded with different clothing (shorts, baggy pants and trousers) to account for

Segment type	Width( $m$ )		Circularity		IAV( $radians$ )	
	$\mu$	$\sigma$	$\mu$	$\sigma$	$\mu$	$\sigma$
Single Leg	0.13	0.03	0.25	0.15	2.23	0.4
Personwide blob	0.33	0.07	0.14	0.09	2.61	0.16
Other	0.22	0.12	0.1	0.11	2.71	0.38

**Table 1:** Table shows average and standard deviations of geometric leg features calculated in our dataset.

variance in the leg parameters. About  $17 \times 10^3$  Single Leg patterns and  $0.6 \times 10^3$  person-wide blobs were manually labeled in the data. In addition,  $120 \times 10^3$  segments were labeled as 'other' or 'not a leg'. The average and variance of the aforementioned geometric features for single leg, personwide blob, as well as other segments are given in Table 1.

For every segment  $S_i$  in a test laser scan, we first extract the geometric features  $f_1^i, f_2^i, f_3^i$ . We then calculate the weighted Mahalanobis distance to the average leg parameters for the each leg pattern:

$$D_{mah}^i = \sum_{j=1}^{n_{features}} w_j \frac{(f_j^i - \mu_j)^2}{\sigma_j^2} \quad (1)$$

where  $w_j$  are the weights for each feature,  $\mu_j$  and  $\sigma_j$  are pulled from Table 1. The resulting Mahalanobis distance is then compared with a detection threshold. If  $D_{mah}^i < Threshold_{leg}$ , the segment  $S_i$  is considered a detection.  $Threshold_{leg}$  defines how many standard deviations away from the average features are allowed. In our implementation, we empirically set the feature weights as:  $\mathbf{W}_{leg} = (0.35, 0.26, 0.39)$ , in the feature order given in Table 1. For normal operation, we set  $Threshold_{leg} = 1.5$ , which accounts for about %95 of the detections. If only one person is being tracked, we use a higher threshold. The reason behind will be explained in Section 4.3.

#### 4.2.1.1 Associating Leg Segments

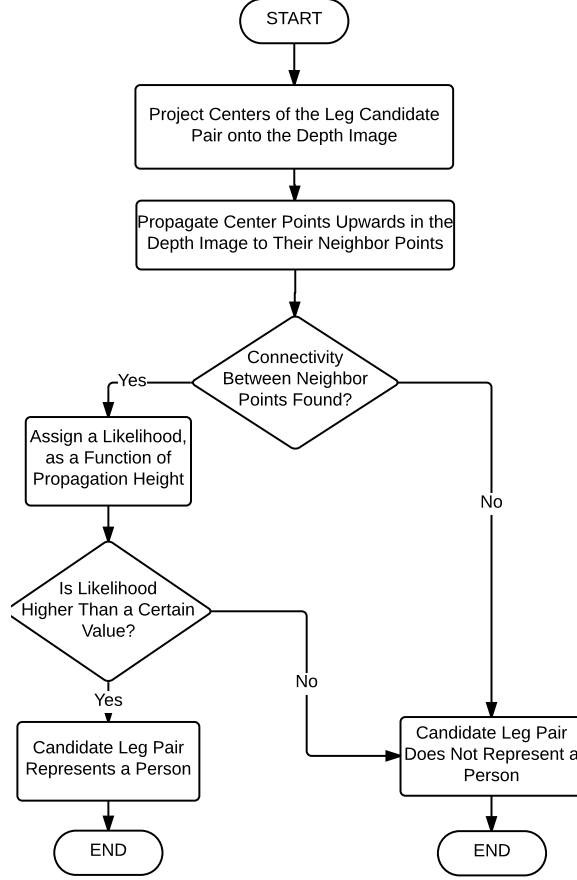

After single leg patterns are detected, we try match the leg segments. We extend our leg detection approach to determine which leg segments are connected. Note that

this method applies if there is a RGB-D camera pointing to the lower body of the human. For each leg segment pair, if both of them are within the FOV of the RGB-D sensor, we use our algorithm to determine whether there is a connectivity between two candidate leg segments. If a connectivity is found, then the leg segments pair is qualified to be a leg segment pair representing a person. See Figure 5 as an example result. Figure 6 shows the flow chart of the association algorithm.

**Figure 5:** Two person detections are seen in this figure. Our leg segment association algorithm propagates pixels vertically from candidate leg segments and connects leg pairs.

First, the centroids each of the two candidate leg segments are found. These points are projected onto the depth image acquired from the RGB-D camera. At each iteration, each leg segment, our algorithm first propagates horizontally to both directions in the depth image, then the center pixel is located and it propagates 1 pixel vertically ( $+z$  direction). If there are no connectivity after a number of iterations, then we conclude that the candidate leg pair does not represent a person. If there is a connectivity at some point, we then assign a likelihood score to the pair as a function of the vertical propagation height. If this score is higher than a threshold, then the algorithm concludes that the leg candidate segments represent a person.

**Figure 6:** Flow chart for determining if two leg segment candidates belong to a person.

The propagation scoring eliminates most of the false positives due to sensor noise and non-human shapes.

#### 4.2.2 Torso Detection

In this section, we describe our torso detection approach. For this detector, we used another Hokuyo UTM 30-LX laser scanner, placed at torso height ( $1.27m$ ). Our approach relies on fitting an ellipse to laser segments and determining the detection result by interpreting the axis lengths (Figure 7). Our torso detector allows us to detect the orientation of the person unlike the laser-based leg detectors, therefore this detector is also suitable for applications that relies on extracting the orientation of the person from a single laser scan.

**Figure 7:** Our torso detector fits an ellipse to the human torso and estimates its position and orientation.

The first step to detect torsos in a laser scan is to segment the laser scan. We use the same segmentation technique used for leg detection, explained in Section 4.2.1. We then fit an ellipse to each laser segment. We use a numerical ellipse fitting method that solves the problem with a generalized eigensystem, introduced by Fitzgibbon [12]. This ellipse fitting method is robust, efficient and ellipse-specific, so that even very noisy sensor data will always return an ellipse. Compared to iterative methods, it is computationally very efficient, therefore the speed of the calculations is limited to the laser scan refresh rate.

The ellipse fitting algorithm provides us with the centroid and orientation of the ellipse as well as the minor and major axis lengths. We use the minor and major axis lengths, as well as the three geometric features introduced in Section 4.2.1 in order to determine if the laser segment is a person. We gathered 450 laser scans while a person stood in front of the sensor and made a one full turn around himself. We calculated the mean and standard deviation of the all five features, which is given in Table 3. For a given laser segment, we find the weighted Mahalanobis distance in Equation 1 to the averaged parameters. If  $Dmah_{torso}^i < Threshold_{torso}$ , the segment is considered a detection. The feature weight constants we used were  $\mathbf{W}_{torso} = (0.19, 0.09, 0.35, 0.24, 0.13)$ , in respective order given in Table 2. These

Torso Features	$\mu$	$\sigma$
Width( $m$ )	0.44	0.12
Circularity	0.32	0.18
IAV( <i>radians</i> )	2.57	0.38
Major axis length( $m$ )	0.39	0.08
Minor axis length( $m$ )	0.17	0.06

**Table 2:** Table shows average and standard deviations of geometric features for a human torso in laser scans.

values were empirically determined, although one can do more sophisticated analysis for optimal weights.

Figure 8 shows how the torso detection rate changes for a given Mahalanobis Distance Threshold in our dataset. What is not displayed in the plot is that higher torso detection rate also means higher rates of false positives. For normal operation, we set  $Threshold_{torso} = 1.25$ , which accounts for about %90 detection rate. If the tracker is dedicated to track only a single person, then we use a higher threshold:  $Threshold_{torso} = 2.5$ . The reasoning behind this threshold selection will be discussed in Section 4.3.

**Figure 8:** Torso detection rate vs weighed Mahalanobis Distance Threshold in our dataset

#### 4.2.2.1 Evaluation of Torso Detection

In order to evaluate the accuracy of the position and orientation estimations of our torso detection method, we collected torso data from 23 people. Subjects were instructed to stand on 4 targets at different distances with 8 different orientations on each target. Experimental setup from the sensor’s view is shown in Figure 9. For each pose at every target, we logged the position and orientation estimation of the torso detector and compared it with ground truth, which is fixed.

**Figure 9:** Experimental setup for the evaluation study of the Torso Detector.

Table 3 shows the angular error at every target distance and human orientation with respect to the laser scanner.

Distance To Laser	N	NE	E	SE	S	SW	W	NW	ALL
1.0m	4°	12°	22°	13°	5°	7°	26°	17°	13°
2.5m	5°	16°	19°	10°	3°	6°	14°	17°	11°
4.0m	4°	10°	30°	16°	7°	11°	21°	17°	15°
5.5m	5°	11°	41°	18°	10°	6°	38°	23°	19°
ALL	4°	12°	27°	14°	6°	7°	24°	18°	14.5°

**Table 3:** Average orientation error of the torso detector with respect to distance from sensor and body pose in a study with 23 people

The average positional error was about 5cm regardless of the distance and the

orientation of the human. The average orientation error throughout all the experiments was  $14.5^\circ$ . Error in orientation, however, varied greatly by pose of the person with respect to the laser scanner. Average error in orientation differed slightly with respect to the distance from the sensor and was the least with  $11^\circ$  when the humans were  $2.5m$  away from the sensor. We attribute to the fact that when humans closer than  $2.5m$  to the laser scanner, it captures more of the arms, which makes the fitted ellipse slightly worse. The orientation of the human with respect to the sensor had a significant effect on orientation error. Least error was achieved when people faced the sensor ( $4^\circ$ ) or the opposite way ( $6^\circ$ ). On the other hand, average orientation error was  $24^\circ - 27^\circ$  when humans are perpendicular to the sensor, because a large portion of the torso is not visible to the laser scanner in that configuration.

### ***4.3 Person State Estimation***

The position and velocity of the person can not be determined by direct observation due to measurement noise and false detections. Therefore there is a need for a filtering algorithm in order to estimate the state of a person. Using a state predictor for human movement has two advantages. First, the predicted trajectories are smoother than raw detections. Smooth tracking helps the robot maintain consistent trajectories for high-level applications such as Person Following (Section 5). Second, it provides a posterior estimation that can be used for data association when there is a lack of matching detections. This allows the tracker to handle temporary occlusions. We use a discrete Kalman Filter [21] to predict the position of a person. There are other types of filtering techniques available in the literature, such as Particle Filters [23]. Since the results of the person state estimator is used by time-critical higher level applications, the tracker should come up with an estimate in real time. Therefore the choice of using Kalman Filters was motivated by its computational efficiency. Efficient person state estimation also increases the safety of the robot, as the robot

can react faster if there are people in close proximity.

According to Hicheur [19], humans tend to maintain a constant speed when they are walking straight and reduce speed while turning. We used constant velocity model which assumes people will maintain their speed. Even though this assumption is not always true, it provides a simple model without sacrificing too much from tracking performance.

The Kalman filter estimates a process as a predictor-corrector cycle using feedback control. The process has two cycling states: time update and measurement update as shown in Figure. Time update projects the state forward by using the current state and error covariance. Measurement update is responsible for the feedback and corrects the previous estimate.

The Kalman Filter is governed by two linear stochastic difference equations:

$$s_k = As_{k-1} + Bu_{k-1} + w \quad (2)$$

$$z_k = Hs_k + v \quad (3)$$

Where  $s_k$  represents the process state at time step  $k$ ,  $A$  is the state propagation matrix,  $B$  relates the optional control input  $u$ ,  $z_k$  is a measurement,  $H$  is the measurement observation matrix.  $w$  and  $v$  represent the process and measurement noises, respectively, drawn from normal probability distributions with zero mean  $N(0, Q)$  and  $N(0, R)$ .

We define the state of a person  $s_k$  at time step  $k$  as:

$$s_k = \begin{bmatrix} x_k \\ y_k \\ \dot{x}_k \\ \dot{y}_k \end{bmatrix} \quad (4)$$

where  $(x_k, y_k)$  is the position and  $(\dot{x}_k, \dot{y}_k)$  is the velocity of the person in Cartesian

Coordinates. With the constant velocity model, the time update equations are:

$$x_k = x_{k-1} + \dot{x}_{k-1}\Delta t_k + w \quad (5)$$

$$y_k = y_{k-1} + \dot{y}_{k-1}\Delta t_k + w \quad (6)$$

$$\dot{x}_k = \dot{x}_{k-1} \quad (7)$$

$$\dot{y}_k = \dot{y}_{k-1} \quad (8)$$

resulting in the following Kalman Filter matrices:

$$A = \begin{bmatrix} 1 & 0 & \Delta t_k & 0 \\ 0 & 1 & 0 & \Delta t_k \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad B = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad H = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \quad (9)$$

where  $\Delta t_k$  is the time difference from the previous detection. A track is lost if there are no detections for a fixed amount of time. At every time update of a filter, if  $\Delta t_k$  is larger than a fixed threshold, the track is killed.

The reason  $B$  vector is zero is that we track people in the world frame and robot motion is already accounted for with robot localization. For this reason, we assume there are no control inputs to our system. The noise matrices we used are:

$$Q = qI_4 \quad R = rI_2 \quad (10)$$

where we used  $q = 0.02$  and  $r = 1.0$  in practice.

Our approach is multimodal in the sense that asynchronous measurements are accepted from different sources as long as they provide a positional estimate in the respective sensor frames. Using the latest localization information, this position is converted to the world frame and then fed as a measurement to the active filters. We apply an additional layer of filtering to every detection before it is considered a measurement. We check if a new detection is in collision with the static map, and if it is in collision, we reject that particular detection. The check against the static

map is fast and helps reduce false positives in practice. We use Nearest Neighbor (NN) data association [4], which is a reasonable compromise between performance and computational cost.

Depending on the task, a single person or multiple people must be tracked. We examine each case below:

- **Single target tracking:** For some tasks, such as person following, dedicated tracking of a single specific user is required and tracking bystanders is not required for task success. In this case, our goal is to keep tracking the specific user, so we significantly relax the detection thresholds of the detectors. Even though doing so results in more spurious detections, we do not start more than a single track. This approach improves the tracking performance of a single person.
- **Multi-target tracking:** When the robot is navigating to a goal point with human bystanders, tracking multiple people at the same time is necessary. Moreover, losing track of a bystander would not be very detrimental to task success. We keep a separate Kalman filter for each tracked person. If a detection is matched to multiple filters, only the closest filter is associated with the detection and the other filters are considered to have no detections for that time step.

#### ***4.4 Face Recognition***

For certain interactive navigation tasks such as finding a specific person, a robot needs to have person recognition capability. Our person recognition approach uses face recognition and optionally shirt color features. We detect faces in RGB images using the popular face detector by Viola and Jones [63]. We use the Eigenface method by Turk and Penland [60] for face recognition. Our approach allows new faces to be trained on-the-fly.

With the *Eigenface* approach, faces are represented in a lower-dimensional space. Sirovich and Kirby [53] showed that dimension reduction method Principal Component Analysis (PCA) can be used on face images to form a set of basis features. The main idea of PCA for faces is to find vectors that best account for variation of face images in all training images. These vectors are called *eigenvectors*. Then a face space is constructed called *eigenfaces* and the images are projected onto this space. Our approach of face recognition works as follows:

**Figure 10:** Example results of our person recognition method is shown in the image. We use *Eigenfaces* face recognition method and optionally shirt color recognition.

1. A person unknown to the system comes up to the robot and initiates training.
2. Robot asks the person to turn his face one side to another, and takes M face and shirt images of this person.
3. Eigenfaces from the entire training set is calculated, and every known face is projected to the corresponding M-dimensional weight *facespace*.
4. After training is completed, face recognition is reactivated.
5. A distance value from face recognition and optionally from shirt color recognition is received and it is thresholded for a decision. An example recognition

result is in Figure 10.

Using the UI of the robot, a user can start training and adjust the information in the person database. The person data is managed by a SQLite database hosted locally on the robot.

Shirt color recognizer can be used when there is little time between the training and recognition. Activating the shirt recognition should improve recognition and reduce false positive detections. We assume a rectangular region below the face captures the shirt (1.5 times below the the face rectangle size). The distribute the histogram into bins using normalized RGB color space because of its relative robustness to lighting. For detection, we calculate the distance between the training histogram to the test histogram using Earth Mover Distance [46]. The color histogram is adaptively updated at every high confidence detection in order to account for illumination changes. The overall person score is calculated by a weighted average of face and shirt distance.

# INDEX

## VITA

Perry H. Disdainful was born in an insignificant town whose only claim to fame is that it produced such a fine specimen of a researcher.

People Aware Mobile Robot Navigation

This is the abstract that must be turned in as hard copy to the thesis office to meet the UMI requirements. It should *not* be included when submitting your ETD. Comment out the abstract environment before submitting. It is recommended that you simply copy and paste the text you put in the summary environment into this environment. The title, your name, the page count, and your advisor's name will all be generated automatically.
